

**INTERFEROMETRIC METHOD AND APPARATUS FOR MEASURING  
PHYSICAL PARAMETERS**

5       The present invention relates to an interferometric method and apparatus for measuring physical parameters.

      Distributed temperature sensors (DTS) are known in which an optical fibre is deployed through a region of interest, light is launched into the fibre, and

10      backscattered optical radiation is used to determine the temperature variation along the fibre. Such distributed temperature sensors have proven to be useful in oil production at determining, for example, flow contributions from different oil producing zones,

15      identifying the location of the ingress of other fluids and the position at which gas breaks out. However, the interpretation of temperature data relies on the contrast between the thermal profile of a flowing well and the geothermal gradient. In those cases where the geothermal

20      gradient is small (e.g. in a horizontal well), then the information may be obtained by inducing a thermal event, which can be tracked, thus revealing the local flow rate.

25      This approach works well in slow-flowing wells. For much higher flow rates some information can be gained from frictional heating effects, but these are very small and the temperature resolution of DTS systems, especially in extended reach-drilling wells, is marginal. The resolution limit of the DTS is of order 0.1°C for long measurement times. This limits the flow resolution to

30      typically 5000 bpd in a 7" bore.

However, it is thought that much more information would be available if the temperature could be measured to a higher resolution, e.g. 0.01°C or better.

Moreover, the DTS is relatively slow when set up for 5 best resolution at long range. It is thought that a fast, high resolution temperature measurement might allow either natural, or induced, thermal fluctuations to be tracked and thus provide a more direct indication of flow in fast-flowing wells.

10 Other measurands would also add to the picture of the well. For example, a measurement of the pressure distribution along the producing interval would allow a precise determination of flow if allied to a density measurement (which might also be obtained from pressure 15 measurements) and some form of mixing. However, pressure sensors with adequate performance for flow determination (e.g. permanent quartz gauges) are expensive and have only limited multiplexing capability.

A solution to these difficulties is now sought on 20 the basis of interferometric interrogation of reflector arrays. This approach is commonly used in fibre-optic hydrophones, which have been deployed for naval applications, as known from Dakin, J.P., Wade, C.A. and Henning, M., 1984, "Novel optical fibre hydrophone array 25 using a single laser source and detector", Electron. Letts, vol. 20, pp53-54, and from Dakin, J.P. and Wade, C.A., 1984, "Optical Fibre Hydrophone Array - recent progress", Proc. 2<sup>nd</sup> Optical Fibre Sensors Conference, Stuttgart, pp375-379.

30 In acoustic measurements, the objective is only to determine an AC signal which is the change in relative phase of the optical reflections from adjacent reflectors in the array. Owing to the AC nature of the signal

processing, many problems that are encountered in static measurements are circumvented.

In an interferometric array, reflectors are spaced by typically a few tens of metres. In hydrophones, the AC signal is obtained by exposing the fibre to strain when an acoustic wave is present; the means of transducing a pressure wave into strain might involve wrapping a fibre on an air-backed mandrel. The fibre itself has a moderate sensitivity to pressure waves, even in the absence of such a mandrel. This signal is detected in the surface instrumentation in the form of a variation of the phase as a function of time. This phase signal, which might stretch over more than  $2\pi$ , conveys information on the instantaneous pressure. The relative phase is, of course, directly related to the optical path length in the section of fibre between the reflectors. However, in acoustic arrays, only changes in the phase are considered. The absolute optical path length is not important and is not measured.

However, if the absolute optical path length between reflectors is known to interferometric precision (i.e. a small fraction of the wavelength of light), then the physical parameters on which it depends (e.g. temperature and strain) can be deduced very precisely. In particular the optical path length depends on the physical length of optical fibre between reflectors and the refractive index separating the reflectors, both of which are sensitive to a variety of external influences. For example, the length changes through thermal expansion and the refractive index varies with temperature through the thermo-optic effect. Likewise, strain obviously affects the length of the fibre, but also the refractive index through the stress-optical effect. In an optical fibre, the index in

question, the so-called effective index, takes a value intermediate between that of the core and the cladding, depending on certain waveguiding effects; the latter effects may themselves be dependent on an external

5 physical parameter, but this is thought to be a second order effect.

One problem is that interferometric sensors provide a periodic response to the measurand and their answer is thus ambiguous. Thus the output of the sensor, as a  
10 function of the measurand, is nominally sinusoidal, each period being referred to as a fringe. In the typical path length between reflectors, there exist a very large number of fringes and it is then difficult to determine on which fringe the interferometer is presently sited.

15 As an example, take a wavelength of 1550nm and a spacing of 10m between reflectors. The number of fringes between the reflections is of order  $1.863 \times 10^7$ . If we assume that the sensor can resolve 1/1000 of a fringe, then the resolution in determining the optical path length would

20 be some  $1:1.863 \times 10^{10}$ . How this resolution translates into a determination of the quantity of interest (e.g.

temperature) will of course depend on the sensitivity of the optical path length to that parameter. In the above example, the temperature resolution would be better than

25 1 mK. However, unless the measurement system is able to determine the fringe order, this very high resolution is meaningless. In contrast, an acoustic sensor merely needs to track changes in the fringe order over an acoustic period (a few ms).

30 The key to the present approach involved in determining the absolute optical length between

reflectors is therefore to resolve the fringe order ambiguity over such a large number of fringes.

According to a first aspect of the present invention there is provided a method of measuring at least one selected parameter at a location within a region of interest, which method comprises the steps of: launching optical pulses at a plurality of preselected interrogation wavelengths into an optical fibre deployed along the region of interest, reflectors being arrayed along the optical fibre to form an array of sensor elements, the optical path length between the said reflectors being dependent upon the selected parameter; detecting the returned optical interference signal for each of the preselected wavelengths; and determining from the optical interference signals the absolute optical path length between two reflectors at the said location, and from the optical path length so determined the value of the selected parameter at the said location.

The step of determining the absolute optical path length preferably comprises carrying out a process in which the derivative of the phase as a function of wavelength is estimated from a subset of the interference signals, using the derivative and an estimated value for the optical path length to estimate the phase relationship between the interference signals, and the phase relationship thus obtained is used to revise the estimated value for the optical path length, the process being repeated for increasing subsets of the remaining wavelengths in sequence, on the basis of the optical path length estimated for the immediately preceding subset in the sequence, thereby to progressively revise the optical path length until it is known to a desired level of

accuracy. In one embodiment, at least one of the subsets comprises a pair of the interference signals.

The optical fibre preferably comprises polarisation-maintaining fibre. Desirably, light is launched into the fibre in such a way that the power of the light signal is substantially equally divided between the orthogonally-polarised propagation modes of the fibre, thereby to interrogate each principal state of polarisation of the fibre simultaneously, the return interference signals from both principal states of polarisation being used separately in the said process for determining the absolute optical path length for each propagation mode independent of the other mode.

Alternatively, light is launched into the polarisation-maintaining fibre in such a way that the power of the light signal is firstly directed entirely into one of the principal states of polarisation and then the other, thereby to interrogate the principal states of polarisation sequentially, the returned interference signals from both principal states of polarisation being used separately in the said process for determining the absolute optical path length for each propagation mode independent of the other mode.

In both cases the effect is to provide two independent interferometric arrays by means of a single fibre, therefore doubling the number of measurements available from which to obtain the optical path length and to separate the effects of multiple measurands.

In some embodiments, the selected parameter may comprise temperature. In this respect, the method may be used to monitor fluid flow by detecting changes in temperature of the flowing fluid. In an example, the region of interest may lie within a pipeline, and the

method may further comprise identifying any temperature variation within the pipeline from the determined value of the temperature at the said location, where temperature variations are indicative of a change of flow 5 of a fluid in the pipeline. The change of flow may arise from a leak of fluid into or out of the pipeline, so that the method comprises identifying a leak at the said location from the identification of a temperature variation at that location. Alternatively, the change of 10 flow may arise from a constriction in the pipeline, and the method comprises identifying a constriction at the said location from the identification of a temperature variation at that location.

In another embodiment, the selected parameter may 15 comprise strain. Birefringent optical fibre can be used to detect strain, so that the optical fibre may be a high-birefringence fibre, the birefringence of which changes in response to strain applied to the optical fibre. In the event that the birefringence of the high- 20 birefringence fibre also changes in response to temperature, the method may further comprise compensating the returned optical interference signal for effects arising from temperature at the said location. This allows the sensitivity of high-birefringence fibre to be 25 exploited to obtain accurate strain measurements, without accuracy being comprised by the cross-sensitivity to temperature that can be demonstrated by such fibre.

An embodiment of the invention used to measure strain may comprise the method wherein the region of 30 interest lies on the surface of a component in an oil well, and the method further comprises identifying movement of the component from the determined value of strain.

In yet further embodiments, the selected parameter may comprise pressure. Advantageously in this regard, the said optical fibre may comprise a side-hole fibre from which accurate pressure measurements can be obtained.

- 5 Further, each sensor element of the fibre may be located within a sealed elliptical tube filled with a pressure-transmitting fluid. This allows each element to be isolated from adjacent elements, so that different pressures can be measured. The pressure-transmitting  
10 fluid allows good pressure communication to the fibre despite the isolation provided by the tubes.

In an example application, the region of interest lies within a pipeline and the method comprises deploying two or more such optical fibres at different azimuths  
15 around an inner surface of the pipeline, and determining a density of fluid in the pipeline from the values of pressure determined for each optical fibre. In an alternative application, the region of interest lies within a pipeline and the method comprises deploying two  
20 or more such optical fibres at difference azimuths around an inner surface of the pipeline, and determining an orientation of the pipeline and/or the optical fibres from the values of pressure determined for each optical fibre.

- 25 In some embodiments, the selected parameter may depend on a localised event moving along the region of interest, and the method may comprise determining the value of the selected parameter over time at more than one said location, and determining the movement of the  
30 localised event from the determined values of the selected parameter. In this way, the rate of flow of a fluid along the region of interest may be measured or monitored, perhaps to detect the presence of an

abnormality that affects flow. The localised event may be a user-induced event, so that the method further comprises inducing the localised event. For example, a volume of fluid may be heated or cooled, or a bubble  
5 created to form a volume of lower density. Whether the event is user-induced or naturally occurring, the localised event may be a volume of fluid within the region of interest that has a different temperature, pressure, or density from surrounding fluid in the region  
10 of interest, the selected parameter being temperature, pressure, or density, respectively.

In further embodiments, at least two selected parameters are measured simultaneously. For example, temperature may be measured with pressure or with strain.  
15 In some cases this can be achieved with a single optical fibre which gives optical interference signals from which more than one parameter may be determined. Alternatively, two fibres may be used, so that the method may further comprise the steps of launching optical pulses at a  
20 plurality of wavelengths into an additional optical fibre deployed along the region of interest, reflectors being arrayed along the additional optical fibre to form an additional array of sensor elements, the optical path length between the said reflectors being dependent upon a  
25 further selected parameter; detecting the returned optical interference signal from the additional optical fibre for each of the preselected wavelengths; and determining from the optical interference signal the absolute optical path length between two reflectors at  
30 the said location, and from the optical path length so determined the value of the further selected parameter at the said location.

The said optical fibre and the said additional optical fibre may share the same fibre jacket.

Alternatively, the said optical fibre and the said additional optical fibre may be constituted by a single  
5 fibre sensitive to both parameters, the fibre having two cores. These arrangements offer ease of deployment, since both fibres/cores can be deployed in a single deployment step.

Moreover, in any of the above embodiments and  
10 examples, the measured value for the parameter may be used to determine the value for a further measurand dependent upon the measured parameter. This increases the scope of the method, since it allows parameters to be measured which in themselves are not operable to affect  
15 the optical path length in a determinable way. For example, the said optical fibre may be provided with a coating which responds to the said further measurand by stretching or shrinking. This will change the strain to which the fibre is subjected, and hence alter the path  
20 length, from which the further measurand can be determined.

Alternatively, the said coating may be electro-strictive, or magneto-strictive. This allows the measurement of electric or magnetic fields. In a further  
25 alternative, the said coating may be sensitive to a selected chemical measurand.

A method embodying the present invention may further comprise the steps of launching optical pulses at a fixed wavelength into the optical fibre and using the returned  
30 interference signal to determine high frequency phase changes. This may be achieved in any convenient manner, for example by providing an auxiliary fibre for the fixed wavelength pulse so that the method may further comprise

the steps of launching optical pulses at a fixed wavelength into an auxiliary optical fibre deployed along the region of interest, reflectors being arrayed along the fibre to form an auxiliary array of sensor elements;

5 and using the returned interference signal from the auxiliary optical fibre to determine high frequency phase changes. The auxiliary fibre may have a coating designed to enhance acoustic sensitivity. Such high frequency phase changes are preferably used to correct for dynamic

10 errors in the returned optical interference signals.

In a method embodying the present invention, the returned optical interference signal is preferably processed to remove the cross-talk term, the cross-talk term being removed for each of n sensor elements by

15 subtracting the cross-talk phasor for the nth sensor element from the measured nth sensor element phasor, the cross-talk phasor being estimated from the phase of all previous sensor elements in the array. The removal process begins with subtraction of the cross-talk phasor

20 for the second sensor element from the measured second sensor element phasor, the cross-talk phasor for the first sensor element in the array being zero.

The embodiments of the first aspect of the present invention are particularly suitable for use in the oil industry, for downhole monitoring applications in well bores. Optical fibres are able to withstand the rigours of the downhole environment to give accurate measurement results, and the method provides techniques for measuring parameters of special interest in oil production,

25 including temperature, fluid flow, pressure and strain.

30 Therefore, the region of interest may lie within an oil well. In some examples, the oil well may be a horizontal oil well.

According to a second aspect of the present invention, there is provided apparatus for measuring a selected physical parameter at a location within a region of interest, which apparatus comprises: an optical fibre 5 for deployment along the region of interest, the optical fibre having reflectors therealong forming an array of sensor elements, the optical path length between the said reflectors being dependent upon the selected parameter; source means operable to launch optical pulses at a 10 plurality of preselected interrogation wavelengths into the said fibre; signal detection means operable to detect the returned optical interference signal for each of the preselected wavelengths; and signal processing means operable to determine from the optical interference 15 signal the absolute optical path length between two reflectors at the said location and to determine from the optical path length so determined the value of the selected parameter at the said location.

In one embodiment, the signal processing means are 20 operable to determine the absolute optical path length by carrying out a process in which the derivative of the phase as a function of wavelength is estimated from a subset of the interference signals, using the derivative and an estimated value for the optical path length to 25 estimate the phase relationship between the interference signals, and the phase relationship thus obtained is used to revise the estimated value for the optical path length, the process being repeated for increasing subsets of the remaining wavelengths in sequence, on the basis of 30 the optical path length estimated for the immediately preceding subset in the sequence, thereby to progressively revise the optical path length until it is known to a desired level of accuracy. In one embodiment,

at least one of the subsets comprises a pair of the interference signals.

The said optical fibre may comprise polarisation-maintaining fibre, and the apparatus further comprises

5 power launching means operable to launch the optical pulses into the fibre in such a way that the power of the optical pulses is substantially divided between the orthogonally-polarised propagation modes of the fibre, thereby to interrogate each principal state of

10 polarisation of the fibre simultaneously; and the signal processing means being operable to use the returned optical interference signals from both principal states of polarisation separately to determine the absolute optical path length for each propagation mode independent

15 of the other mode. Alternatively, the said optical fibre may comprise polarisation-maintaining fibre, and the apparatus further comprises a polarisation modulator operable to launch the optical pulses into the fibre in such a way that the power of the optical pulses is

20 firstly directed entirely into one of the principal states of polarisation of the fibre and then the other, thereby to interrogate the principal states of polarisation sequentially; and the signal processing means being operable to use the returned optical

25 interference signals from both principal states of polarisation separately to determine the absolute optical path length for each propagation mode independent of the other mode.

In some embodiments, the parameter comprises

30 temperature. In this context, the region of interest may lie within a pipeline, and the signal processing means may be further operable to identify any temperature variation within the pipeline from the determined value

of the temperature at the said location, where temperature variations are indicative of a change of flow of a fluid in the pipeline. The change of flow may arise from a leak of fluid into or out of the pipeline, and the 5 signal processing means may be operable to identify a leak at the said location from the identification of a temperature variation at that location, for example. Alternatively, the change of flow may arise from a constriction in the pipeline, and the signal processing 10 means may be operable to identify a constriction at the said location from the identification of a temperature variation at that location.

In other embodiments, the parameter comprises strain. The optical fibre may comprise a high- 15 birefringence fibre, the birefringence of which changes in response to strain applied to the optical fibre. In the event that the birefringence of the high birefringence fibre also changes in response to temperature, the signal processing means may be further 20 operable to compensate the returned optical interference signal for effects arising from temperature at the said location.

The region of interest may lie on the surface of a component in an oil well, and the signal processing means 25 may be further operable to identify movement of the component from the determined value of strain.

In further embodiments, the parameter comprises pressure. In such embodiments, the said optical fibre may comprise a side-hole fibre (see Xie, H.M., Dabkiewicz, 30 Ph., Ulrich, R. and Okamoto, K. "Side-hole fibre for fiber-optic pressure sensing", Optics Letters 1986, vol. 11, p 333). Further, each sensor element of the fibre may

be located within a sealed elliptical tube filled with a pressure-transmitting fluid.

Applications of apparatus configured in this way in those in which the region of interest lies within a pipeline; the apparatus comprises two or more such optical fibres for deployment at different azimuths around an inner surface of the pipeline; and the signal processing means is operable to determine a density of fluid in the pipeline from the values of pressure determined for each optical fibre. Other applications include those in which the region of interest lies within a pipeline; the apparatus comprises two or more such optical fibres for deployment at different azimuths around an inner surface of the pipeline; and the signal processing apparatus is operable to determine an orientation of the pipeline and/or the optical fibres from the values of pressure determined for each optical fibre.

In some embodiments, the selected parameter may depend on a localised event moving along the region of interest, and the signal processing means may be operable to determine the value of the selected parameter over time at more than one said location, and to determine the movement of the localised event from the determined values of the selected parameter. The localised event may be a user-induced event. The localised event may be a volume of fluid within the region of interest that has a different temperature, pressure, or density from surrounding fluid in the region of interest, the selected parameter being temperature, pressure, or density, respectively.

In some examples, the apparatus may further be for measuring a second selected physical parameter at the

location within the region of interest, wherein said optical path length between the said reflectors is further dependent upon the second selected parameter; and the signal processing means is further operable to 5 determine the value of the second selected physical parameter from the determined absolute optical path length.

Apparatus embodying the present invention may further comprise at least one additional optical fibre 10 provided for deployment through the region of interest, reflectors being arrayed along the additional optical fibre to form an additional array of sensor elements, the said additional optical fibre being suitable for measurement of a different physical parameter to that for 15 which the other fibre is provided. Preferably, the fibres share the same fibre jacket. Alternatively, they may be constituted by a single fibre sensitive to both parameters, the fibre having at least two cores.

Apparatus embodying the present invention may be 20 operable to use the measured value for the parameter to determine a value for a further measurand dependent upon that parameter.

In this regard, the optical fibre may be provided 25 with a coating which responds to the further measurand by stretching or shrinking. For example, the coating may be electro-strictive, magneto-strictive or designed to be sensitive to a selected chemical measurand.

In apparatus embodying the present invention the source means are preferably also operable to launch light 30 at a fixed wavelength and at a varying wavelength into the fibre, the signal processing means being operable to use the interference signal from interrogation at the fixed wavelength to determine high frequency phase

changes. In such a case the apparatus may further comprise an auxiliary optical fibre for deployment through the region of interest, reflectors being arrayed along the fibre to form an auxiliary array of sensor elements, the source means being operable to launch the fixed wavelength signal into the auxiliary fibre.

Preferably, the auxiliary fibre has a coating designed to enhance acoustic sensitivity. The apparatus embodying the present invention may also launch light at a variable wavelength concurrently with the launch of the fixed wavelength. The signal processing means may be further operable to use the high frequency phase changes to correct for dynamic errors in the returned optical interference signals.

The signal processing means may be further operable to process the returned optical interference signal to remove the cross-talk term, the cross-talk term being removed for each of the n sensor elements by subtracting the cross-talk phasor for the nth sensor element from the measured nth sensor element phasor, the removal process beginning with subtraction of the cross-talk phasor for the second sensor element from the measured second sensor element phasor, the cross-talk phasor for the first sensor element in the array being zero.

In some embodiments, the region of interest may lie within an oil well. The oil well may be a horizontal oil well.

According to a third aspect of the present invention, there is provided a method of measuring a parameter in an optical fibre interferometric array, comprising launching optical pulses into the array, creating an interference signal within sensor elements in the array, detecting the phase of the interference

signals, wherein the returned optical interference signal is processed to remove the cross-talk term, the cross-talk term being removed for each of n sensor elements by subtracting the cross-talk phasor for the nth sensor element from the measured nth sensor element phasor, the removal process beginning with subtraction of the cross-talk phasor for the second sensor element from the measured second sensor element phasor, the cross-talk phasor for the first sensor element in the array being zero.

Reference will now be made, by way of example, to the accompanying drawings, in which:

Figure 1 shows a schematic diagram of an optical fibre sensor array;

Figure 2 shows a plot of unwrapped phase against wavelength;

Figure 3 shows a plot of phase against wavelength;

Figure 4 shows apparatus for use in carrying out a method embodying the present invention;

Figure 5 shows apparatus for use in carrying out a method embodying the present invention in more detail; and

Figure 6 shows a pressure sensor.

Fig. 1 illustrates an array of reflectors  $2_0, 2_1, \dots, 2_n$ , separated by a distance L (approximately constant), imposed onto an optical fibre. The section of fibre between each pair of reflectors  $2_0, 2_1$ , etc. constitutes a sensor element. The reflectors are intended to be quite weak, for example of order 0.1% reflectivity, partly to reduce losses to subsequent sensor elements, but also to reduce cross-talk between the elements.

Cross-talk between adjacent sensor elements is a seriously limiting factor in acoustic sensor arrays in

the purely reflectometric arrangement. However, the simplicity of the arrangement, including the reduced number of fibres to be taken to the surface and absence of components such as downhole couplers make it extremely 5 attractive in the present context. The trade-off is that the reflectivity of each reflector must be reduced to limit cross-talk, which of course then impacts on the signal-to-noise ratio that can be achieved. However in this case, provided that high-performance acoustic 10 measurements are not required, then the simplicity of the downhole configuration make it extremely attractive.

In order to address the cross-sensitivity between the different factors affecting optical path length, it is proposed to use polarisation-maintaining fibres and to 15 measure the optical path length separately for each of the two principal states of polarisation (SOP).

A polarisation-maintaining fibre is one which is designed to be highly asymmetric; the asymmetry ensures that a large difference exists between the propagation 20 constants of orthogonally-polarised modes. Owing to the difference in propagation constants, there is minimal power conversion between the modes, which thus propagate essentially independently one of the other. The fibre can be designed to be strongly differentially sensitive to 25 certain measurands for the two SOPs. The side-hole fibre is one such example, where the optical path-length difference between the principal SOPs varies markedly as a function of external pressure. An auxiliary benefit of using this polarisation-maintaining fibre (which is 30 significantly more expensive than conventional fibre) is that the problem, commonly found in hydrophone arrays, of ensuring that the polarisation states of the light from adjacent reflectors are aligned, is circumvented.

Of course, using the difference between the optical path lengths in a birefringent fibre is a well-known method of performing interferometry in that it ensures a common path for the arms of the interferometer and also 5 (in birefringent fibres) the state of polarisation of the combining waves is well controlled. This approach is known in the literature as polarimetry. It is however fundamentally different from what is proposed here: conventional polarimetry forms the difference in optical 10 path length between the two optical paths directly in the optical domain and only this difference is measured. In contrast, in the present proposal, the absolute optical path length of each optical path is measured and the resulting information is processed digitally to provide 15 independent determinations of two measurands. Alternative approaches are based on comparing the relative path lengths of the two lowest modes of a fibre, usually designed to guide only a few such spatial modes.

Assuming the fibre 1 is therefore to be 20 polarisation-maintaining, we shall consider each polarisation separately. As implied in Fig. 1, the spacing between reflectors is approximately constant. Although multiples of L would also work, only those sections between reflectors 2 spaced by L would be 25 measured.

As mentioned above, interferometric sensors provide a periodic, and thus ambiguous, response. In order to remove the ambiguity, the present invention repeats the measurement at a series of different carrier frequencies, 30  $f_c \pm f_1$ . The process of establishing a relationship (without  $2\pi$  ambiguity) between the phase at each of the carrier frequencies is referred to as unwrapping. In this way, the variation of the phase as a function of

carrier frequency can be determined. Its derivative is the group delay,  $\tau = L/c \times N$ , where  $N$  is the group index and  $c$  the speed of light in vacuo. Since the relationship between group and phase indices is known, or can be measured, the phase index can be obtained. Alternatively, the group data can be used directly as an indicator of the physical parameters that are required to be measured.

In particular, for each frequency, the following holds:

10

The total phase difference between adjacent reflectors separated by distance  $L$  is given by:

$$\Phi(\lambda) := 4 \cdot \pi \cdot L \cdot \frac{n(\lambda)}{\lambda} \quad (1)$$

15 where  $n(\lambda)$  is the effective refractive index for the waveguide structure. Differentiating with respect to wavelength  $\lambda$ , gives:

$$\frac{d}{d\lambda} \Phi(\lambda) := -4 \cdot \pi \cdot \frac{L}{\lambda^2} \cdot N(\lambda) \quad (2)$$

20

Here  $N(\lambda)$  is the group index of refraction (which dictates the speed of information transfer, as opposed to that of the waves for the phase index  $n(\lambda)$ ).

25 Combining (1) and (2), it follows that:

$$\Phi(\lambda) := \lambda \cdot \frac{n(\lambda)}{N(\lambda)} \cdot \frac{d}{d\lambda} \Phi(\lambda) \quad (3)$$

Thus, according to an embodiment of the present invention, the following steps are carried out in order to obtain a value for the absolute optical path length:

Firstly, light at a first series of wavelengths is launched into the fibre to thereby acquire a series of phase measurements at various wavelengths. Some of these must be closely-enough spaced that they can be unwrapped (i.e. the phase determined) unambiguously from available *a priori* knowledge of L. Typically, L will be known *a priori* to a few %.

Then, using two or more such closely-spaced wavelengths,  $d\Phi/d\lambda$  is estimated, and using this value for  $d\Phi/d\lambda$ , and the known values for  $n(\lambda)$  and  $N(\lambda)$ , equation (3) is used to estimate the phase  $\Phi(\lambda)$  at each of the two wavelengths.

Then, from inverted equation (1) a revised estimate of L at one or both of the wavelengths can be obtained on the basis of the estimated value for  $\Phi(\lambda)$ .

The newly-estimated value for  $\Phi(\lambda)$  is then used to improve the accuracy of  $d\Phi/d\lambda$  and the steps above are repeated for all the data from the measurements at the first series of wavelengths. The process is then repeated at a second series of wavelengths, shifted from the first series of wavelengths, until the phase has been unwrapped over the range of interrogation wavelengths, as illustrated for example in Figure 2, and the unwrapped phase is used to improve the estimate of the optical path length until this estimate is of adequate quality to unwrap the phase to DC (zero frequency).

To unwrap the phase down to DC, it is assumed that the unwrapped phase less a phase synthesised from the current length estimate must be flat with wavelength.

Thus, a fit of this residual phase vs. wavelength may be used to correct the length estimate and thus compute the number of wavelengths (or fringes) in the sensor element. That is, measuring the slope of the function given by the 5 difference between the actual unwrapped phase and the unwrapped phase calculated from the latest estimate of the optical path length, as illustrated for example in Figure 3, gives a measure of the correction required to ensure that the unwrapped phase is equal to that which is 10 calculated from the optical path length.

Once the absolute phase is known at any (and thus all) wavelengths, the length is calculated for each wavelength sampled. The average of all such calculated lengths provides the best estimate for the optical path 15 length (assuming equal uncertainty for each phase measurement).

Thus, the above procedure essentially bootstraps from closely spaced frequencies (which have little risk of unwrapping errors, but provide poor resolution of the 20 length) to increasing frequency spacings which provide a longer baseline to estimate phase differences.

Ultimately, it is necessary to span a sufficiently wide range that the phase can be unwrapped with confidence down to DC. However the frequency sampling pattern must 25 be such that the entire chain from the closest frequencies to the most widely spaced are accurately unwrapped.

The procedure may be generalized and a set of data acquired at frequencies of appropriate spacing such that 30 the phase relationship between all data in the set can be established and from this phase relationship the absolute length L between the reflectors determined to within one fringe. The specific unwrapping procedure detailed above

is but one example of an approach to determining the absolute length.

Errors in the results can be decreased by increasing the number of frequencies sampled. This, however has the  
5 drawback that the acquisition time is increased, and this may be undesirable since the extreme sensitivity of the system implies that all measurements must be made far faster than the measurand is likely to vary the phase by a significant amount. It may therefore be necessary to  
10 accept a certain error rate and then apply a non-linear filter to reject outliers.

The optical arrangement which is proposed to accomplish these measurements is shown in Fig.4. A narrow band laser 3 is used as an oscillator and delivers a very  
15 pure, single frequency, tone to the rest of the system at a carrier frequency  $f_c$ . The laser 3 is tunable (i.e. of variable frequency) so that successive measurements can be accomplished with different carrier frequencies. The interrogating light is preferably a dual pulse, timed so  
20 that the reflection of the first pulse off the remote reflector 2 of any given sensor element coincides with the reflection of the second pulse off the nearer of the reflector pairs. The frequencies of these pulses are  $f_2$  and  $f_2 + \Delta f$ , where the frequency difference  $\Delta f$  is small  
25 compared with optical carrier frequency. Whilst it is not necessary for the pulses to be at slightly different frequencies, a frequency shift between the pulses may make the interpretation of the phase simpler, lifts certain ambiguities and makes the signal recovery less  
30 dependent on the strength of the reflectors 2. For a spacing  $L=10m$ , the corresponding round-trip time between reflectors 2 is roughly 100 ns and a frequency shift of 10 MHz is required for the signal to show a full cycle

(the seven cycles shown in the diagram thus correspond to  $\Delta f \sim 70\text{MHz}$ ). The beat frequency is exactly equal to the difference in frequency of the two pulses and is thus known to a high level of precision. It follows that by 5 sampling the optical return signals, the relative phase for each reflector pair can be determined modulo  $2\pi$ . Thus, the continuous output of the laser 3 is converted to a dual pulse, with a defined frequency difference  $\Delta f$  between the two pulses, by a dual-pulse modulator 4. The 10 resulting pulse pair is amplified to a peak power approaching the non-linear limit by an amplifier 5, bandpass-filtered by bandpass filter 6 to eliminate unwanted amplified spontaneous emission, and launched into the sensor array 9 via some form of directional 15 coupler 7 (e.g. fibre coupler, circulator, or bulk-optic arrangement). Preferably, all the fibre components must be made from polarisation-maintaining fibre and the power launched on-axis. At some point – either in the instrument or immediately prior to the array 9 (or at a 20 convenient place in between) the power is converted to equal power in the orthogonal modes, most easily accomplished with a splice 8 at  $45^\circ$  between successive fibre sections. This means that the two interferometers in each sensor element formed by each principal SOP are 25 interrogated simultaneously. Alternatively, it would be possible to use a polarisation modulator in the instrumentation to switch the SOP from one principal axis to another and interrogate the SOPs sequentially. The light returned from the sensor array 9 is sent, via the 30 directional coupler 7 and an optical preamplifier 10, to polarisation splitter 11, which selects the orthogonal linear states of polarisation and sends each to a separate detection system 12a, 12b.

As explained above, the principle of the measurement technique requires that the frequency of the carrier be varied. There are several forms of tunable laser available commercially. For example, distributed feedback 5 (DFB) lasers made from rare-earth-doped optical fibre exhibit narrow linewidth and are tunable either through stretching (e.g. with piezo-electric actuators) or by changing their temperature. Alternatively, special designs of semiconductor DFB lasers allow separate 10 frequency and power control. It may be preferred to use one or more fixed-frequency lasers, and then modulate their output to generate electronically-controlled sidebands which are then filtered to isolate programmable 15 optical frequencies. This is the approach illustrated in Fig. 5.

The output of the laser 3 is passed through a modulator 31 which generates side-bands, for example an integrated-optic modulator which presently has the widest modulation bandwidths. The position of the sidebands is 20 determined by a first RF frequency  $f_1$  input to the modulator 31 and can thus be controlled. An acousto-optic deflector (AOD) 33 used as a modulator is configured in double-path configuration both to chop a pulse pair from the output of the first modulator 31 and also to provide 25 a differential frequency shift  $\Delta f$  between the pulses in the pair by control of a second RF frequency  $f_2$ . Use of the AOD 33 in double-pass configuration doubles the frequency shift  $\Delta f$  applied to  $f_2$ . A circulator 32 is used to access the AOD 33, but could of course be replaced by 30 a coupler at lower cost if the accompanying loss in signal strength was acceptable (or polarisation-maintaining circulators are not available).

Alternatively, the construction could be made in bulk optics.

Tunable fibre Bragg gratings 36a, 36b are provided and are used to select just one of the sidebands. They  
5 are placed between stages of amplification 34, 37, which bring the signal up to a few hundred mW, close to the non-linear limit. This is then launched into the sensor array 9, possibly through a download consisting of polarisation-maintaining fibre. At some point, either at  
10 the entrance to the download or where the sensor array 9 proper starts, there must be a ~45° rotation of the fibre axes so as to ensure that power is launched in both axes. On the return path, the reflected light from the sensor array 9 - after passing through a directional coupler 37  
15 and in this embodiment an optical preamplifier 38 - is sent to a polarisation splitter 39, which selects the orthogonal linear states of polarisation and sends each to a separate detection system, 40a, 40b.

The frequency range that the system can span will  
20 determine its ability to resolve ambiguity over a wide range of distances L. As illustrated, variation of the RF frequency f2 will allow the frequency to be swept over a small range (typically, ± 10-15% of the centre RF frequency f2). Wider frequency deviation may be achieved  
25 by varying f1. For example, integrated optic modulators (IOM) are available with bandwidths approaching 20GHz. Thus a given sideband can be swept over a range of, say, 10GHz and by selecting the other sideband a total span approaching 40GHz can be covered. However, this is  
30 unlikely to be sufficient to resolve fringe ambiguities in sensor elements of L=10m. A wider span still can be achieved either by addition of further lasers at selected wavelengths different from the first, or by tuning the

wavelength of the original source, as illustrated in Fig.  
3. Modelling suggests that two sets of samples each  
spanning 40GHz and separated by 300-400 GHz would be  
adequate to resolve fringe ambiguities in L=10m, assuming  
5 an uncertainty on each phase reading of order 10 mrad.

Whichever approach is adopted to generating a  
programmable optical frequency, the laser(s) should be  
locked to precise, stable, wavelengths (this is  
particularly important where more than one source is  
10 used, or a single source is tuned).

There are two principal reasons for stabilising the  
laser frequency. The first is to ensure that the several  
measurements of the phase are mutually consistent in  
order that these measurements samples might be  
15 reconstructed into an absolute measurement of L. Unless  
the successive measurements apply to source frequencies  
which are known to a high precision, their relationship  
will be indeterminate and therefore it will not be  
possible to resolve the fringe ambiguity. This imposes a  
20 strenuous, but short-term only, requirement on the laser  
frequency stability. The second reason is that the laser  
wavelength is the length reference in the system, the  
"ruler" against which the measurements of L are compared.  
Of these two, it is the short-term requirement that is  
25 the more important: failure to maintain a consistent  
frequency over the short term will prevent our getting a  
measurement at all. In contrast, a slow drift of the  
central frequency will affect only the accuracy and in  
the case of differential measurements may not be  
30 critical.

The requirements on short-term frequency stability  
are that a value of order 100kHz in the time of a  
measurement (c. 6 ms) is needed in order to avoid a

degrading the effective signal-to-noise ratio of each shot. (For pre-amplified systems, the demand is a further order of magnitude in frequency stability (i.e. 10 kHz or thereabouts) to avoid degrading the estimate of the 5 phase). In terms of long-term stability, we would need a frequency accuracy of 3MHz (in the case of 10 metre long sensor elements) to ensure an accuracy of 1mK on the temperature reading.

There are a number of well-established methods for 10 referencing lasers to fundamentally-defined frequencies.

A measurement method embodying the present invention will now be described in further detail.

Firstly, a series of measurements are taken at a frequency  $f_c$ . In turn, the carrier frequency  $f_c$  equals  $f_0 \pm f_1 \pm f_2 \pm \Delta f$  and is determined by the frequency of the 15 laser ( $f_c$ ) shifted by one or more modulators ( $f_1$ ,  $f_2$ ) and the modulation frequency being varied by a small amount ( $\Delta f$ ) between pulses, the variation of  $f_c$  being sufficiently small that the phase relationship between 20 successive measurements is known. The frequency interval might be chosen to ensure that the phase shift occasioned by the change in frequency is less than  $2\pi$  radians, but equally phase shifts of a few cycles might prove to be manageable. For  $L=10m$ , a frequency change of about 10MHz 25 corresponds to one full cycle.

Provided that the relationship between successive phase measurements can be determined with absolute confidence (with no  $2\pi$  ambiguity), then the largest frequency interval meeting this criterion should be 30 selected, since the derivative of the phase vs. frequency function can then be determined with a minimum number of measurements.

In practice, the actual length between reflectors should be known to a few %, simply on the basis that this value exceeds the long-term strength of the fibre. As an example of the relationship between the frequency range 5 and the accuracy of the estimate of L, the number of cycles that can be passed in each frequency jump is roughly the reciprocal of the confidence with which the length is known *a priori*. Five cycles appears to be a safe limit, and thus a series of 10 equispaced 10 measurements would cover 50 cycles. Thus for a signal-to-noise ratio of 100:1, the relative error on L, derived from the slope of the phase/frequency function, would be of order 5 ppm. This should give adequate confidence to jump a different frequency band. However, the use of a 15 remotely-pumped amplifier is likely to improve the resolution by a further factor of > 10.

In one approach to the planning of the frequencies used to probe the array, when the first series of measurements have been completed, a major shift in the 20 frequency of the carrier is effected and a further sequence of phase measurements vs. carrier frequency is carried out.

Measurements are repeated at further major increments in source frequency as required for the 25 absolute optical path length to be known to a desired level of accuracy.

Provided that the fringe order phase can be tracked over the major jumps in carrier frequency, there is no need to measure the phase at intermediate frequencies. To 30 judge the consistency of such a set of measurements, take again the case of L=10m. Assume that 10 measurements are taken at an approximate phase separation of 5 cycles, i.e. 50MHz apart, covering  $100\pi$  radian. The averaging

intrinsic to the fitting process is expected to bring the uncertainty on the slope down to of order 5ppm; this results in L being determined to a similar relative precision, i.e. 0.05mm. If the major frequency jumps are 5 of order 10GHz, this corresponds to 1000 cycles, and given the precision with which L can be known from the short-span frequency scan, then the fringe order after the frequency jump can easily be correlated to that of prior measurements. (In the foregoing numerical example, 10 after the jump, the new phase should be predicted by dead reckoning to < 2% of one cycle, easily enough to unwrap the phase between frequency jumps, but not necessarily down to DC).

By using the maximum span of a currently-available 15 IO modulators (40GHz, including a side band on either side of the carrier), the phase should be known to 0.001 cycles in 4000, i.e. 1: 4,000,000 - not quite sufficient to determine the fringe order (assuming that the optical path length is within a few % of a nominal value). It 20 follows that in general either greater frequency shifts still are required or further measurements must be made with a different source frequency.

The number of measurements required will depend, at least to some extent, upon the signal processing scheme 25 adopted. It is thought that using one particular signal processing scheme, some 170 measurements will be required, which at a pulse repetition rate of 33 kHz will take < 6ms. At this rate, acoustic signals will also be picked up and some low-pass filtering may be required.

30 The foregoing assumed that the two polarisations travel without mixing. If this is not the case, then power is converted from one SOP to another and this can

lead to partial (or even complete) fading of the interference and this is also a source of noise.

This risk of loss of polarisation contrast must be addressed by ensuring that the birefringence of both the sensing and the downlead fibre is sufficient to avoid polarisation conversion. This is relatively achievable for standard high-birefringence fibre. In the case of a side-hole fibre, it implies that there must be a strong built-in birefringence - in the same sense as the pressure induced birefringence. It also means avoiding tight bends and micro-bends. The latter requirement may run counter to the need to seal the pressure between sensor elements, in the application to pressure measurements as discussed below.

By definition, in birefringent fibre, one mode travels faster than its orthogonal counterpart. This polarisation walk-off effect is cumulative from one reflector to the next. If the difference in the optical distance seen by the two orthogonal modes becomes significant compared to the distance between reflectors, it must be taken into account in the signal processing. It might be possible to compensate for this effect by exchanging the fast and slow axes, by forming splices in which one fibre is rotated by 90° with respect to the other.

Potentially, the most serious of all extraneous effects is the effect of changes in the phase during the acquisition of the measurement data. If the optical path length is changing very fast, it might be difficult for the surface electronics to acquire a consistent set of measurements between successive pulse repetition periods. If this is the case, it may be necessary to speed up the pulse repetition frequency, or possibly to reduce the

frequency increments to provide a higher degree of redundancy in the information gathered.

In practice, these fast transients might come either from a rapid change in the desired measurand, e.g.

5 temperature, or from an external perturbation, e.g. acoustic interference. Ensuring that the measurand is tracked implies a sampling rate much faster than that at which a significant phase change occurs. As an example, it is shown below that a 10m gauge length will exhibit a  
10 phase change of a few 100 cycles for each K of temperature change. If sampling at 10 kHz and assuming 10 measurements are used in small-increment scanning, this implies that 1 K/s temperature ramp will cause an error of a few tenths of a cycle over the 50 cycles used in the  
15 example above. This level of error may be marginally capable of confusing the fringe-tracking algorithm and thus represents a rough estimate of the limiting rate of change in temperature which the system is expected to be able to handle.

20 More serious is the possible effect of acoustic noise coupling. If this turns out to be a significant problem, then it will be necessary to retain the individual phase measurements acquired over a reasonable time interval and average the phase obtained for each  
25 carrier frequency over that interval, thus, in effect, low pass-filtering the acoustic response. The drawback is of course that the transient response of the sensor array will also be slowed. However, if these acoustic effects turn out to be significant, acoustic information can also  
30 be derived from the data acquired

The intrinsic relative phase sensitivity of a conventional fibre is  $2.2 \times 10^{-12}/\text{Pa}$ . Thus in our case, the total phase is  $1.87 \times 10^7$  fringes (each equal to  $2\pi$

rad) and thus the sensitivity to acoustic noise is  $42\mu\text{rad/Pa}$ . Whether or not this is significant depends entirely on the noise level downhole due to pump vibrations, flow noise and so on. The measurement and processing can be made more robust by minimising the unwanted phase variation for each sample. In turn, this may be achieved by increasing the pulse repetition frequency (PRF) and increasing the number of measurements used to derive L. The PRF is normally limited by the time taken for a pulse to travel from the surface electronics to the most remote point of interest and to return to the opto-electronics. If only the final section of the sensing fibre is of interest (and that contains reflectors), then the PRF can be increased above this limit: consider for example an array of 3km length with a 7km downlead. The total length (10km) would normally restrict the PRF to 10kHz, to ensure that only one pulse is present in the fibre at any one time. However, the light travelling to and from the array is of no interest and - subject to any splices being of adequately low reflectivity - therefore pulses can be launched at a rate limited only by the need to have only one pulse in the sensor array at any one time. In this example, the PRF is then limited to 33kHz.

The pressure sensitivity of the fibre is also dependent on its coating. The example given above is for a bare fibre and applies at least approximately to a fibre with a thin, hard coating, e.g.  $10\mu\text{m}$  of polyimide.

In order to handle acoustic transients, it might be desirable to arrange to have two parallel acquisition arrangements, one at a fixed frequency and one with a variable interrogating optical frequency. The latter is used as explained above to deduce absolute path lengths.

The former is used to sense acoustically induced phase changes and thus provides information to correct dynamic changes to the static measurands and at the same time provides a passive acoustic signal output.

5 Since the approach is capable of quite fast update rates, it offers the possibility of measuring pressure, or strain, from DC to a few kHz, i.e. from static measurements into the area where acoustic information is present. This data is obtained essentially "for free",  
10 although it may be preferable to use pairs of fibres, in the same cable structure (e.g. tube), one with a coating designed to minimise acoustic sensitivity (for DC measurements) and another used for acoustic measurements, with coatings designed to enhance acoustic sensitivity.

15 Another difficulty which exists is the cross-talk between sensor elements which arises because, for the more remote reflectors, the power reflected at a time corresponding to the position of these reflectors is intermingled with power arriving at the same time, but  
20 having undergone multiple reflections off nearer reflectors. The problem is well illustrated in patent specification US 5,987,197. There are two effects arising from multiple reflections. The first is an increase in the shot noise, resulting from a greater level of optical power impinging on the detector. A more serious issue is  
25 that these unwanted reflections each shift the phase of the reflected signal slightly. Given that the system is interferometric, these spurious signals are proportional to the electric field amplitude, not optical power, and  
30 their effect, when considering the strength of the double reflection, is thus proportional to the reflectivity of a reflector, not the square of the reflectivity. In long arrays, there are many paths that can contribute to the

signal arriving at a particular time. The problem is similar to that facing television reception in city centres, where the direct signal from the transmitter is mixed with other signals which have reflected from buildings in the vicinity.

5 In US 5,987,197 the proposed solution is to make successive sensor elements from pairs of gratings, each pair being at a different wavelength band. Whilst this is effective at reducing the cross-talk, it is extremely 10 inconvenient in the context of the approach proposed here, because each different wavelength implies either a different source or scanning one source at another wavelength band, thus multiplying the acquisition time by the number of wavelength bands used in the system. In the 15 case of US 5,987,197, this is probably not an issue because that concept is aimed at acoustic arrays only and there is therefore no scanning of the source as envisaged. Consequently, each wavelength band can be as narrow as the grating manufacturing technology and 20 constraints relating to the environment of use permit (in practice, the temperature-dependence of the central wavelengths of the gratings would be a serious issue in oilfield applications).

Instead, it is proposed here to determine and 25 correct the cross-talk term. Whilst cumbersome, this is possible to do because the first sensor element has no cross-talk, the second element can only suffer cross-talk from the first, and so on. It is therefore possible to subtract the cross-talk phasor on the second element due 30 to double reflections in the first element from the measured second element phasor. The same process can be repeated successively for each array element, with, of course increasing complexity with increasing element

number. Ultimately, the complexity and, more importantly, the accuracy of the correction may become intractable for long arrays, which may force a sub-division into smaller arrays, the arrays being interrogated at, for example, 5 different wavelengths. Nonetheless, the corrective approach outlined above should allow the number of wavelengths used in the system to be reduced significantly and also allow arrays consisting of identical wavelengths to be constructed, with the 10 significant benefit of requiring only a single grating between sensor elements, rather than two as in US 15,987,197.

It would even be possible gradually to shift the grating wavelengths, such that there is significant 15 overlap between adjacent gratings (since each must be wide enough to reflect at the design reflectivity over a range of wavelength sufficient for the laser frequency scan to determine the absolute sensor element unambiguously). With such an approach the laser would be 20 scanned over a wider wavelength range than the reflectivity of a single grating, which restricts the number of alternative paths which can interfere with the signal for a particular array element.

If measurement time is of the essence, a certain 25 degree of parallelism can be introduced by arranging for multiple acquisition sub-systems (detector, preamplifier and A/D converter with relating digital memory and data-reduction) to acquire different wavelength bands simultaneously. The source is then adapted to generate 30 multiple pulse pairs (one in each of the wavelength bands into which the array is sub-divided) at slightly different times (to avoid optical non-linear effects).

The signal-to-noise ratio (SNR) to be expected has been calculated for arrays having reflectors each of 0.2% reflectivity. The case of a passive down-hole array (7km downlead followed by 3km of sensing array) leads to an 5 anticipated SNR of 100:1; the inclusion of a remotely pumped amplifier immediately prior to the sensor array 9 leads to an improved SNR of around 1500:1.

From a separate simulation, again for L=10m and sampling at 100 to 200MSPS, the phase resolution derived 10 from a given SNR, the resulting phase resolution is of order 0.8/SNR radian. Thus for a SNR of 100:1, the fringe resolution is of order 0.0015 fringe for each of the frequencies. The uncertainty on the measurement of the group delay then depends on the uncertainty of slope of 15 the fitted data.

In a sensor array 9 where the sensor elements are 10m long, and light at 1550nm is used (for which the group index N=1.484), it is believed that the phase can be resolved to 1/1000 fringe, allowing the temperature to 20 be determined to 4  $\mu$ K.

Such sensitivity indicates an improvement greater than four orders of magnitude in the ability to read temperature array data. Such improvement would overcome the deficiencies in measuring temperature in horizontal 25 well applications with current distributed temperature sensing technology. The fibre could possibly be blown or pumped into the well, provided that the reflectors are re-coated in such a way as to make the coated diameter the same as the fibre before gratings are inscribed.

30 Another application where the ability to detect minor temperature variations is extremely valuable is for detecting leaks in pipelines. It should provide the ability to detect much smaller gas leaks and also the

location of minor constrictions in oil flowlines to identify early precipitation of waxes or hydrates, when there is plenty of time to rectify the situation.

In the case of measuring strain, it is proposed to  
5 use the change in birefringence of a high-birefringence fibre. These fibres are designed to include a high level of internal asymmetric stress caused by differential expansion coefficients. The birefringence is highly sensitive to temperature, but also to strain since the  
10 Poisson's ratio for the glass forming the stress-applying sectors and the remainder of the structure are markedly different. For a fringe resolution of 1/1000 fringe, the strain resolution is expected to be of order 2 nε.

However, the temperature cross-sensitivity will need to  
15 be taken into account and compensated.

Given the predicted refresh rate, the measurement of strain according to the approach presented above would easily allow tracking of movements in risers, flowlines etc. This would allow potential damage (e.g. caused by  
20 land movement) to be identified before it occurs. There is also an application in measuring the pipe itself and it has been claimed that the measurement of strain over the surface of the pipe allow problems such as blockages and corrosion (which causes swelling) to be identified.  
25 Clearly any measurand that can be converted to strain is applicable to this measurement.

In the case of measuring pressure, one of the solutions is to use a side-hole fibre. These fibres exhibit a strong sensitivity of the birefringence to  
30 isostatic pressure (and a relatively low temperature sensitivity of the birefringence). Experience in these fibres indicates a pressure sensitivity of order 1/20 fringes/psi/m. Thus for L = 10m and a fringe resolution

of 1/1000 fringe, the pressure resolution expected is 0.002 psi in 5ms.

As indicated above, the use of a side-hole fibre would allow the pressure in each hydrocarbon zone to be measured, possibly to the same performance level as expected from crystal quartz gauges. One of the problems with distributed pressure sensing is the communication with the reservoir pressure. One solution is illustrated in Fig.6. In essence, the sensing fibre 1 is placed in an elliptical tube 4, having seals 42 at each end, which is filled with a pressure-transmitting fluid, e.g. silicone oil. The tube 41 is sealed at each of the reflectors 2 and is over-stuffed with excess fibre to ensure that reasonable levels of strain are not transferred to the fibre 1. Pressure applied to the tube 41 is transferred to the sensing fibre 1 by elastic deformation of the tube 41: isostatic pressure tends to flatten the tube 41 (minor diameter will reduce still further), because the cross-sectional area of an ellipse is reduced as the major/minor axis ratio increases (i.e. the shape is flatter). This, in turn, tends to reduce the volume sealed in the tube 41, thus transferring the applied pressure to the fibre 1. The tube 41 thus acts as a stiff bellows.

This device, where the sensor elements are long, is particularly appropriate to horizontal wells, where gravity/density effects are small.

Of course, siting several tubes at different azimuths around the tubing would allow a determination of the fluid density and thus the water hold up. As a rough guide, for a 6 5/8" tubing, the pressure differential across a vertical diameter is expected to be of order 0.20 psi, compared with 0.30 psi for mineral-laden water.

Thus, with a resolution of 1 mpsi (which would take <1 s integration time), water hold-up could be measured up to a few %. However, in order to achieve this level of precision, the two fibres must be calibrated to the 5 accuracy indicated above. This would probably have to be achieved with some sort of intervention, e.g. by ensuring that, temporarily, the fluid between the sensors is known.

With the anticipated pressure resolution, such sets 10 of pressure sensors arrays, e.g. fitted at 90° around a production tubing, would allow the orientation of the four elements to be determined, purely from gravity. In turn, if sensor elements are integral to the tubing (as opposed to strapped on, possibly imprecisely), then the 15 orientation of the tubing itself can be determined. This might then allow the tubing to be designed with orientation-specific characteristics (e.g. slots facing upwards only).

At the speed at which the transducer is expected to 20 respond, it should be possible to track induced events. With a much improved sensitivity and speed of response, the approach is expected to work at far higher flow rates, allowing increased use of flowmeters based on hot-wire anemometry. In addition, the induced event need not 25 be restricted to cooling or heating; for example, if a large bubble (or fluid with markedly different density from the production fluid) were injected into the fluid flow, then the density, as read between vertically-separated array elements (possibly by using separate 30 arrays disposed around the periphery of the tubing) should detect a differential pressure change and thus the passage of a bubble.

In addition, it might be possible to track naturally occurring events. There exist thermodynamic fluctuations in most properties (certainly local temperature, pressure, density) of fluids. For example, imperfect 5 mixing of fluids of different temperature, or density or pressure, may all be detectable at the :K, mpsi level.

Fibres with coatings designed to respond to particular measurands by stretching or shrinking could be applied to this interrogation approach.

- 10 For example, consider resistive arrays, which attempt to measure the approach of a waterfront to a borehole. In essence, these arrays measure very small voltages. If the fibre coating were electro-strictive (e.g. piezo-electric), then a small voltage applied 15 across the coating could be used to sense small voltage. In this respect, the carbon coating applied to certain fibre types is conductive (at least enough for the slow response times needed here), which means that the bottom electrode is already present on such fibres.
- 20 Sensitivities reported [See Imai et al, Journal of Lightwave Technology, v LT5, p 926-931, 1987] for PVDF piezoelectric coatings are of order  $10^{-5}$  rad/m/(V/m) for a 60 $\mu$ m coating thickness. Thus in this case, a 1mV voltage applied across such a coating would result in a phase 25 change of about 1.6 mrad. If the resolution is of order 0.01 rad, 36 measurements would be required to resolve 1mV in a 10m sensor element, i.e. about 3.6 ms at a PRF of 10 kHz, i.e. a 1 hour averaging time required to reach 1  $\mu$ V. It is clear that very careful temperature 30 compensation would be required to reach this level of accuracy. Similarly, magneto-strictive coatings have been used to measure magnetic fields and they could be used in

this context for the measurement of magnetic fields and electric current.

Alternatively, specialised coatings designed to respond to specific chemical species by straining the  
5 fibre could be employed as chemical detectors.

The present system can thus be used to measure any two of the following parameters simultaneously: pressure, temperature, and strain, which measurements as disclosed above can be used to infer other parameters (such as  
10 chemical, electrical, and magnetic properties).

It has been shown above how pressure and strain can be measured together with temperature. It may be necessary to measure all three parameters simultaneously. This might involve fibres having different pressure and  
15 strain sensitivity combinations. One example would be a "pure" side-hole fibre and another side hole fibre which might also contains stress-applying sectors. Ideally these fibres would be held together (e.g. in the same jacket, such as in a 2-fibre ribbon) or a more complex  
20 glass structure might contain several cores, say one core sited between a pair of side-holes and the other between a pair of stress-applying sectors.
